Impetigo

Impetigo is the most common bacterial infection of the skin, and is usually seen in children. Almost always, it is caused by *Staphylococcus aureus* or streptococci, or a combination of the two. The source of these infections is mainly nasal or perianal colonisation, and infection is acquired by skin-to-skin contact, or from contact with nasal carriers.

There are two types of impetigo:

- **Impetigo contagiosa**, which presents as crusted lesions and characteristic honey-coloured exudates. The most affected area is the face, especially around the nose and mouth (see Figure 1).
- **Bullous impetigo** is usually caused by *Staphylococcus aureus*. It presents with blisters that contain a turbid fluid. These blisters rupture and leave a “collarette” of scale surrounding the blister roof at the periphery of the ruptured lesions (see Figure 2). Some lesions may enlarge to form polycyclic patterns (see Figure 3). They occur anywhere, and may be widely and irregularly distributed.

Mild and localised disease can be treated with either mupirocin ointment or fucidic acid ointment. Mupirocin is highly bactericidal to all common, primary skin pathogens. It induces a rapid bacteriological and clinical response that is equal to, or surpasses that of other topical and oral agents. The clinical efficacy of mupirocin has been proven in a large number of studies, and in particular, in the management of impetigo and furunculosis.

Systemic antibiotics such as cloxacillin are reserved to treat severe disease. Mupirocin nasal ointment can be used to eradicate persistent nasal carriage. Vancomycin, clindamycin and linezolid are used for cases of methicillin-resistant *Staphylococcus aureus*.

Ecthyma

Ecthyma is a pyogenic infection of the skin. It is characterised by the formation of adherent crusts, beneath which ulceration occurs. The aetiology is similar to that of impetigo. Some cases are caused by *Streptococcus pyogenes*, some by *S. aureus*, and others by both. This means that the infection may be synergistic. Ecthyma occurs in both children and adults. Predisposing factors are poor hygiene, malnutrition, immunosuppression and skin trauma.

Lesions start as pustules, or small blisters, on an erythematous base. These rupture to form hard crusts of
Management of ecthyma gangrenosum involves identification of any underlying immune deficiency, debridement, and the administration of intravenous antibiotics. Current recommendations advocate the use of aminoglycosides like amikacin or gentamycin, and anti-pseudomonal \( \beta \)-lactam agents such as piperacillin (or tazocin) and ceftazidime. Quinolones (i.e. ciprofloxacin) also have anti-pseudomonal properties.

**Erysipelas**

Erysipelas is a bacterial infection of the dermis and upper subcutaneous tissue. It presents with a well-defined, raised edge, an indication of more superficial dermal involvement. Erysipelas is usually a streptococcal disease. \( S.\ aureus \) is occasionally isolated from lesions of erysipelas.

Clinically, erysipelas present as an erythematous swelling with a raised, well-defined edge. In severe cases, blistering can occur. Erysipelas starts abruptly with acute systemic symptoms that may become severe with fever. The legs are the most commonly affected site, and an obvious wound can usually be identified as a possible site of inoculation. Erysipelas affects the face too, but here, the traumatic site of entry is generally not easily identifiable. Specimens for bacteriological examination should be collected from blister fluid or ulcerated surfaces. Blood cultures should also be taken.

In mild cases, oral monotherapy with cloxacillin is usually adequate, as it is bactericidal to both streptococci and staphylococci. Clarythromycin may be given in penicillin-allergic patients. For severe cases with possible complications, intravenous treatment with benzylpenicillin is indicated.

**Cellulitis**

Cellulitis is an acute, subacute or chronic inflammation of loose connective tissue, but generally the term applies to the inflammation of subcutaneous tissue in which an infective, generally bacterial cause is proven or assumed. The causative organism is \( S.\ aureus \) either alone, or in combination with streptococci. \( Haemophilus\ influenzae \) type b is an important cause of facial cellulitis in young children up to the age of two years, but rarely causes cellulitis in adults.

Other bacteria are occasionally implicated in cellulitis in specific immunosuppression or exposure settings. These include \( S.\ pneumoniae \) (the sinuses), \( Aeromonas\ hydrophila \) (complicates injuries that have been contaminated by soil), \( Pasturella\ multocida \) (inoculated by animal bites) and \( Pseudomonas\ aeruginosa \) (causing gangrenous cellulitis and ecthyma gangrenosum).

Cellulitis may be caused by \( Acinetobacter\ calcoaceticus \) and \( S.\ epidermis \), as well as \( Bacteroides\ fragilis \) and \( Yersinia\ anterocolitica \). A case of anaerobic cellulitis produced...
by a clindamycin-resistant *Clostridium perfringens* has also been reported.\textsuperscript{16} Cellulitis can occur following infection of a surgical wound, ulceration or traumatic skin injury. Other predisposing factors are diabetes mellitus, immunosuppression, and venous or lymphatic insufficiency.

Clinically, cellulitis presents as an erythematous swelling with diffuse poorly demarcated edges (see Figure 5), as opposed to erysipelas which has well-defined edges. Severe cellulitis may blister and progress to dermal necrosis. Lymphangitis and lymphadenopathy can result, while fever and malaise occur frequently. Periorbital cellulitis is particularly common in children. It usually follows trauma to the eyelids, which are then infected by streptococci or staphylococci.

![Figure 5: Cellulitis on the cheek.](image)

A clinical assessment should guide empiric treatment as to the likely pathogenic organism. If monotherapy is required, oral cloxacillin is sufficient. Clarythromycin can be given to penicillin-sensitive patients. Initial treatment must cover both streptococci and staphylococci. *H. influenzae* should be borne in mind when treating facial infections in young children. Severe cases will require intravenous treatment with cloxacillin or benzylpenicillin.

Since the aetiology of cellulitis is broad, and in case an unusual organism is implicated, active attempts to identify the causative organism are necessary. Treatment should be given for five to ten days, but for longer periods if there are complications such as fasciitis, myositis, subcutaneous abscesses and septicemia. In recurrent cases, long-term penicillin can be given orally to prevent attacks.

Recurrent episodes of cellulitis have been associated with post-cellulitic oedema. Oedema is a risk factor for recurrent disease.

**Furuncles and carbuncles**

A furuncle is a hair follicle abscess, resulting from infection with *S. aureus*. In contrast to superficial Staphylococcal folliculitis, furuncles are deep-seated. They are rare in childhood, but common in adults. The infecting strain of *S. aureus* is usually present in the nostrils or the perineum.

This implies that repeated and heavy inoculation of chronic carriers may result in the development of furunculosis.\textsuperscript{4} Furunculosis is common in the HIV setting.

A furuncle starts as a small follicular inflammation, later becoming an abscess, which then ruptures and heals, leaving permanent scars. Lesions can be single or multiple, and tend to appear in crops (see Figure 6). Fever and constitutional symptoms may be present. Cheek lesions can develop into cavernous sinus thrombosis, although this is rare.\textsuperscript{4}

![Figure 6: Furunculosis in an elderly diabetic patient](image)

Treatment of mild localised lesions with mupirocin ointment is usually adequate. When severe disease with multiple lesions is a factor, for example in immunocompromised patients, systemic treatment with cloxacillin may be necessary.

Carbuncles result when a group of contiguous hair follicles become deeply infected with *S. aureus*. The condition is characterised by intense inflammatory changes in the surrounding connective tissues, as well as the subcutaneous fat. A carbuncle starts as a small painful erythematous nodule that is dome-shaped and tender to the touch. Inflammatory changes and necrosis of the intervening skin may occur. There may be high fever and malaise. Carbuncles are treated with cloxacillin or other penicillinase-resistant antibiotics. In some cases, incision and drainage may be necessary.

**Staphylococcal scalded skin syndrome**

Staphylococcal scalded skin syndrome is a generalised, confluent, erythematous superficial exfoliation that commonly occurs in neonates and young children, following infection by certain strains of toxin-producing *S. aureus*. It is rare in adults. Predisposing factors include immunosuppression, renal failure and malignancy.

Outbreaks in nurseries have been reported.\textsuperscript{11} The staphylococcal infection usually originates at a distant focus, like the pharynx or nose. Septicaemia or cutaneous
infection may also be the cause. Other primary infection foci from the urinary tract, umbilicus and conjunctivae can also lead to staphylococcal scalded skin syndrome. The associated strain of staphylococcus releases exfoliatin, an epidermolytic toxin that causes skin desquamation. The disease starts abruptly with fever, skin tenderness and erythema, sparing palms, soles and mucous membranes. This differentiates it from toxic epidermal necrolysis, which is drug-induced. The erythema in staphylococcal scalded skin syndrome is often accentuated in flexural and periorificial areas.

Generalised exfoliation follows within a few hours or days, leaving raw, painful areas. Pus swabs from the skin lesions usually yield staphylococci. This is because the desquamation is mediated by toxins which are disseminated haematogenously. The same toxins are present in bullous impetigo which may be regarded as a localised form of staphylococcal scalded skin syndrome. If it can be identified, the staphylococci can be isolated from the original infection site.

Early administration of intravenous antibiotics, such as cloxacillin or a cephalosporin, results in a good recovery within seven to ten days. Intravenous penicillinase-resistant, anti-staphylococcal antibiotics, supportive skin care, as well as fluid and electrolyte management in the setting of disrupted skin barrier function, will ensure rapid recovery. In children, where there is usually no underlying predisposing factor, the prognosis is good.

Staphylococcal scalded skin syndrome epidemics in neonatal nurseries can occur. Typically, the source of such outbreaks are nursery or maternity staff infected with, or colonised by epidemolytic toxin-producing S. aureus. Identification of health care workers who are colonised by, or infected with toxigenic strains of S. aureus, is an integral part of managing these outbreaks. Infection control measures, including strict enforcement of chlorhexidine hand washing, oral antibiotic therapy for infected health care workers, and the application of mupirocin nasal ointment for the eradication of persistent nasal carriage, are usually adequate.
